

# Update on HVStripV1 analysis

LUIGI VIGANI  
OXFORD

# Current Situation

2

- ▶ MB01, MB03 and MB06 had the big capacitor removed
  - ▶ More than 60V bias applied
- ▶ MB03 and MB06 irradiated at Birmingham at about  $10^{15} n_{eq}$
- ▶ MB03 and MB06 in freezer at Oxford
- ▶ MB06 to be sent to Glasgow

# Single Injection

3

- ▶  $\text{Fe}^{55}$  peak reproduced with injection at a fixed voltage (calculated from the number of electrons produced by the  $\text{Fe}^{55}$  X-ray)

Peak should be in the same position,  $\text{Fe}^{55}$  sigma should be higher due to statistical fluctuations

(2,1)

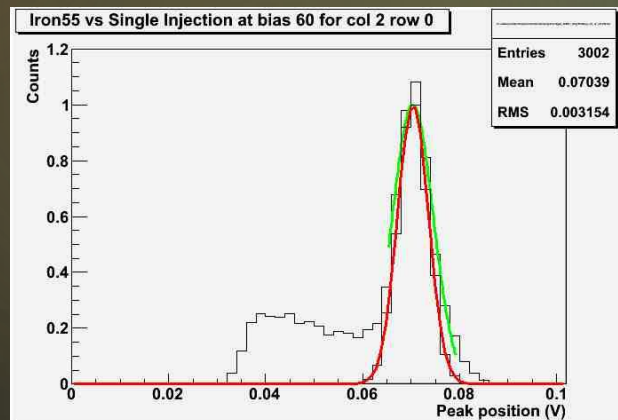

4 Pixels scanned  
Bias 60V

Green: Iron55      Red: single injection

- Peak positions match within 10%

(2,0)

- Noise due to statistics goes as square root of number of electrons ( $\sim 1680$ ) and must be subtracted in square
- Given that,  $\text{Fe}^{55}$  noise is 20% higher than injection

(16,1)

(16,0)

# Single Injection at higher bias

4

**Bias 80V** (2,0)

(2,1)

(16,0)

(16,1)

**Bias 90V**

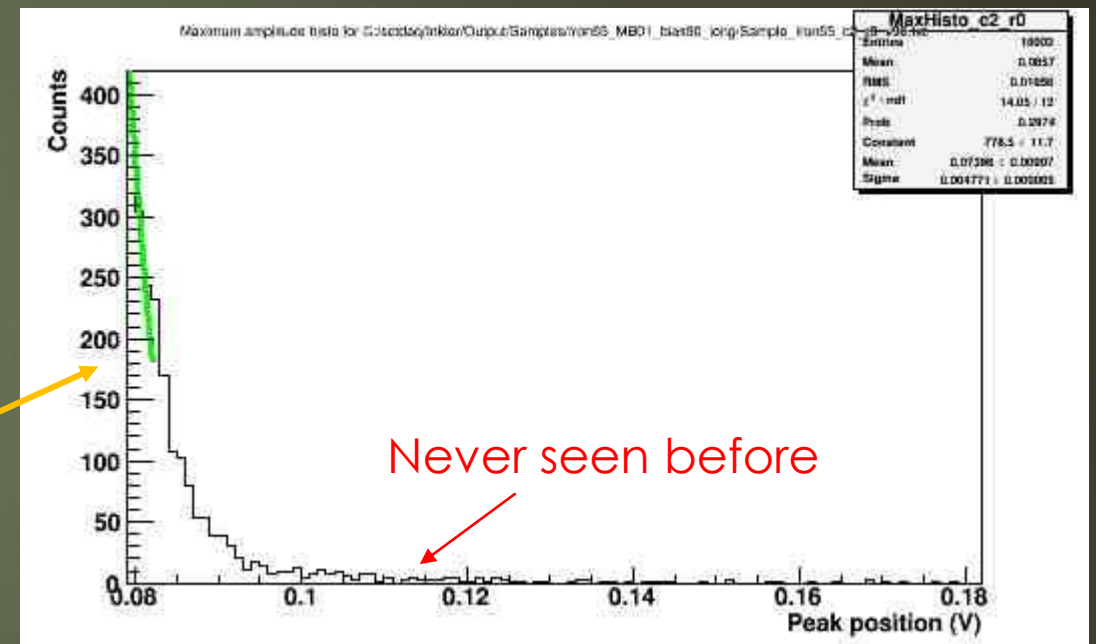

$\text{Fe}^{55}$  shifts to higher value with respect to single injection

# Single Injection at higher bias

5

Other noticeable fact: a tail appears at bias 90:

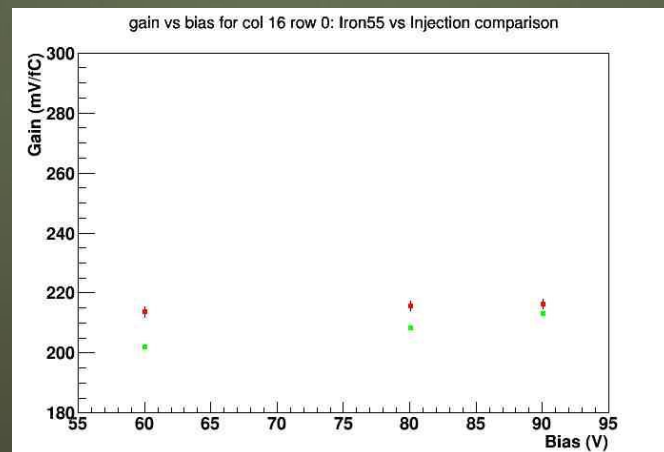

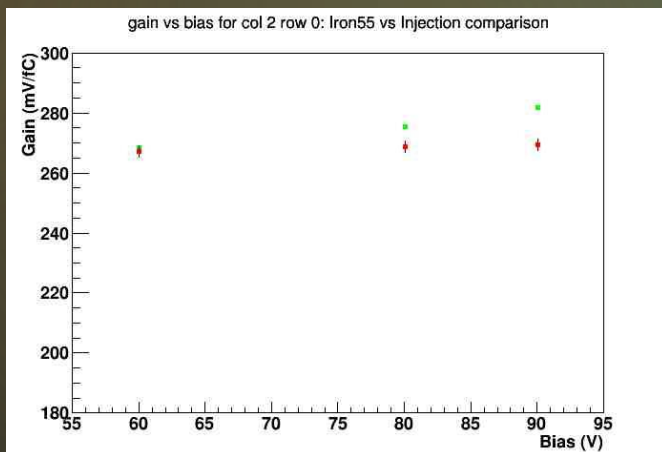

In addition: at 90V leakage current was already getting higher (about 80 nA)

# Bias scan on MB01: gain

6

## Comparison between the two usual ways of calculating the gain ( $\text{Fe}^{55}$ and multiple injections)

- Slight difference between  $\text{Fe}^{55}$  and injection
- $\text{Fe}^{55}$  increases faster than injection

We have to take into account the intercept in the gain fit with injection:

Green: Iron55

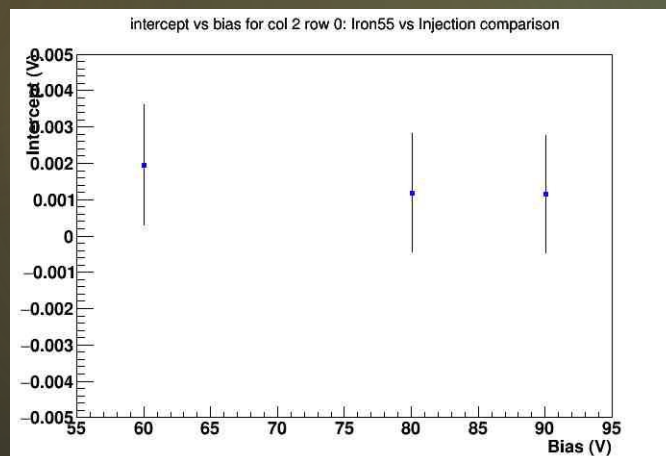

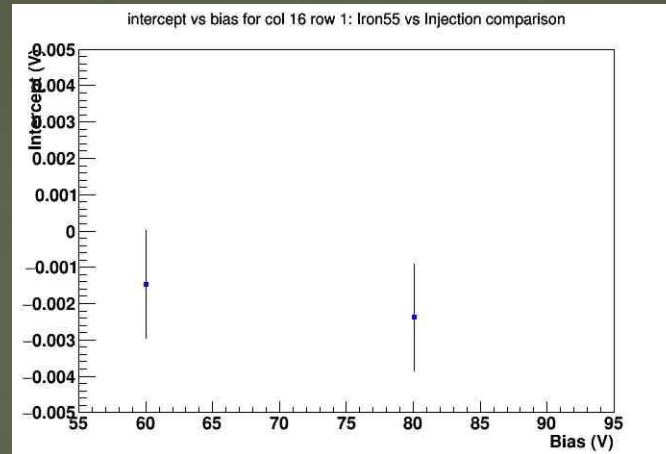

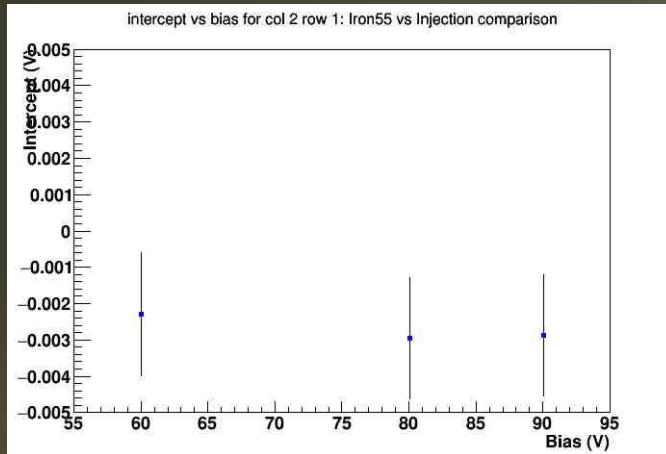

Red: injection

# Bias scan on MB01: gain intercept

7

## Intercept parameter as a function of bias voltage

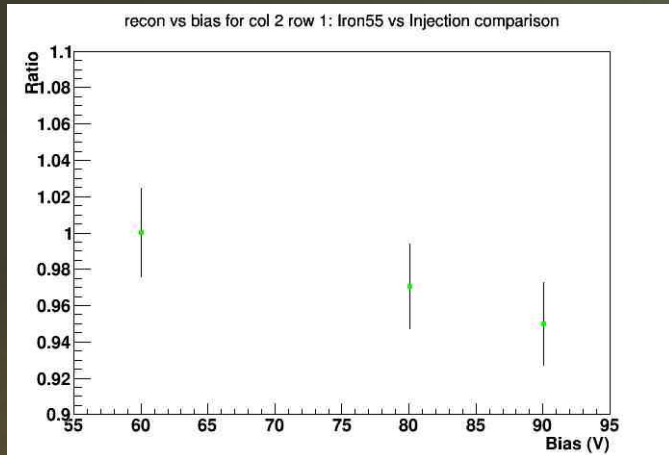

A slight variation:

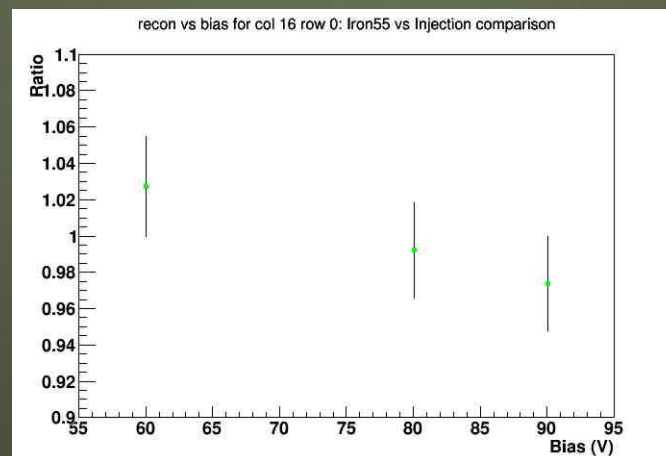

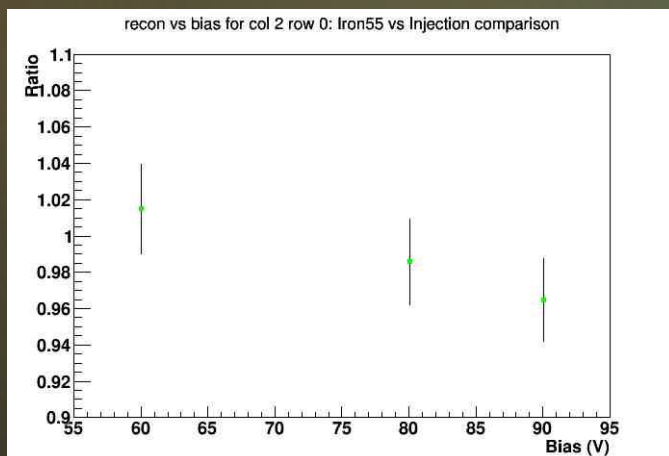

- Calculate the expected injection voltage that reproduces the  $\text{Fe}^{55}$  peak (as in slide 3)
- Predict the output
- Divide it with the observed one (real source)
- This value should be 1...

# Bias scan on MB01: predicted over observed

8

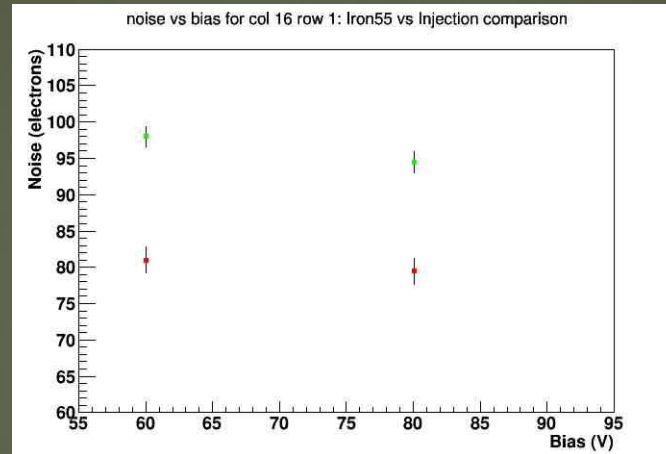

- It is about 1 for 60 and 80V bias
- It decreases as the bias increases (extra charge production?)
- It is significantly below 1 at 90V bias

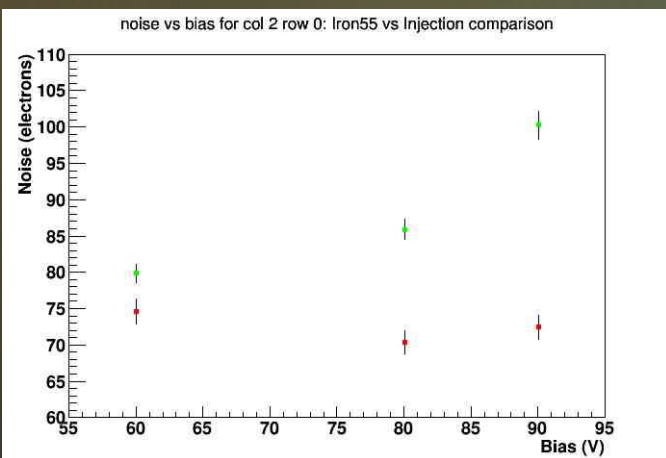

# Bias scan on MB01: noise

9

- $\text{Fe}^{55}$  noise significantly higher, even after subtracting the statistical contribution
- Injection noise can be considered flat

Green: Iron55

Red: injection

# Current scan

10

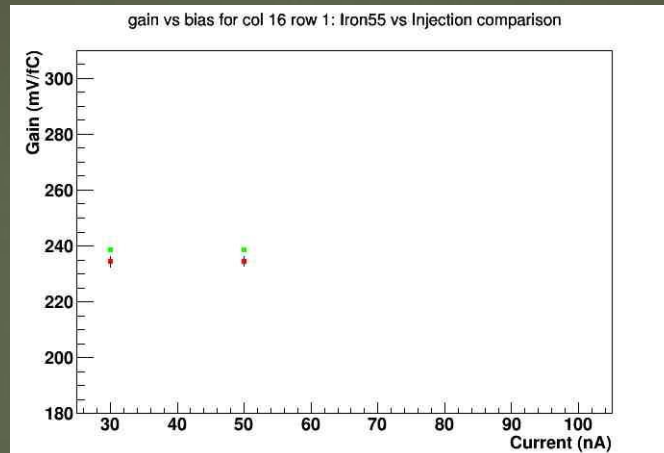

- ▶ For higher biases: HV supply in current mode:

Leakage Current	Bias
-30 nA	-93.9V
-50 nA	-94.7V
-100 nA	-95.7V

# Current scan on MB01: gain

11

Comparison between the two usual ways of calculating the gain ( $\text{Fe}^{55}$  and multiple injections)

- $\text{Fe}^{55}$  flatter
- Closer distributions

Green: Iron55

Red: injection

# Current scan on MB01: noise

12

- Fe<sup>55</sup> noise significantly higher
- Injection noise can be considered flat
- Fe<sup>55</sup> noise almost flat

# Some data on irradiated MB06

13

Good news: leakage current at  $-40^{\circ}\text{C}$  is less than 10 nA (HV supply's resolution)

Calibration with injection taken at 60V bias.

DAC 6 set to 5:  
lower s/n ratio

Regular  
behavior

# Some data on irradiated MB06

14

Bad news: still no  $\text{Fe}^{55}$  peak visible.

(2,0) with DAC6 set to 5

(2,0) with DAC6 set to 60

(2,1)

Distributions of time difference between one event and the next one:

The time difference distribution is still the one typical of a radioactive source...

# Conclusions

15

- ▶  $\text{Fe}^{55}$  spectrum compared with a calibrated single injection
- ▶ MB01 analyzed with charge injection and  $\text{Fe}^{55}$  up to more than 90V bias
- ▶ Breakdown at about 95V.
- ▶ For higher bias, MB01 analyzed with HV power supply in current mode
- ▶ MB06 shows a good calibration profile, but still no  $\text{Fe}^{55}$  peak.
