NEUTRINO 2018, Heidelberg, 3-10 June

Conventional neutrino oscillations

- Convetional approach to neutrino oscillations relies on a number of assumptions:
  - Flavor state is a superposition of mass states with identical energies:

$$|\nu_\alpha\rangle = \sum_{i=1}^{3} V^*_{\alpha i}\,|\nu_i(p)\rangle$$

  - Production and detection proccesses occur coherently.
  - Mass states travel at speed of light.
- This leads to the extensively experimentally studied oscillation probability

$$P_{\alpha\beta}(L) = \sum_{i,k=1}^{3} V^*_{\alpha i}V_{\beta i}V^*_{\beta k}V_{\alpha k}\exp\left(-2\pi i\frac{L}{L^{\text{osc}}_{ik}}\right), \quad L^{\text{osc}}_{ik} = \frac{4\pi E}{\Delta m^2_{ik}}$$

- There are internal inconsistencies within this approach:
  - Distance L can't be defined with delocalized states.
  - The coherence of production and detection should be proven.
  - Equal energy assumption is not Lorentz-invariant.

Neutrino oscillation with wave packets

- The issues above can be addressed when one considers neutrino flavor state as coherent superposition of mass states with different momenta:

$$|\nu_i(k)\rangle \to \int \frac{dk}{2\pi} f(k,p,\sigma^2)|\nu_i(k)\rangle$$

- Assuming form factor is Gaussian the oscillation probability reads:

$$\text{P}_{\alpha\beta}(L) = \sum_{k,\,j=1}^{3} \frac{V_{k\beta}V^*_{\alpha k}V_{j\alpha}V^*_{\beta j}}{\sqrt[4]{1+\left(L/L^{\text{d}}_{kj}\right)^2}} \exp\left[-\frac{\left(L/L^{\text{coh}}_{kj}\right)^2}{1+\left(L/L^{\text{d}}_{kj}\right)^2} - \text{D}^2_{kj}\right] \text{e}^{-i(\varphi_{kj}+\varphi^d_{kj})}$$

$$\varphi^{\text{d}}_{kj} = -\frac{L/L^{\text{d}}_{kj}}{1+\left(L/L^{\text{d}}_{kj}\right)^2}\left(\frac{L}{L^{\text{coh}}_{kj}}\right)^2 + \frac{1}{2}\arctan\frac{L}{L^{\text{d}}_{kj}}, \quad \varphi_{kl} = 2\pi\frac{L}{L^{\text{osc}}_{kj}},$$

- $\sigma_{rel} = \sigma_p/p$ is the relative momentum dispersion of wave packet. σ_p is the intrinsic momentum dispersion of wave packet. It depends on the kinematics of production and detection proccesses. In this work $\sigma_p = \text{const}$ is assumed.
- $L^{\text{coh}} = \frac{L^{\text{osc}}_{kj}}{\sqrt{2}\pi\sigma_{\text{rel}}}$ is coherence length. At this distance separation of wave packets due to different group velocities suppresses interference between mass states.
- $L^{\text{d}}_{kj} = \frac{L^{\text{coh}}_{kj}}{2\sqrt{2}\sigma_{\text{rel}}}$ is dispersion length of wave packet. At this distance coherence between mass states is partially restored due to spacial broadening of wave packet.
- $\text{D}^2_{kj} = \frac{1}{2}\left(\frac{\Delta m^2_{kj}}{4p^2\sigma_{\text{rel}}}\right)^2$ suppresses the coherence of mass states due to spacial localization of production and detection regions.

What do we know about σ_p?

- No first principle QFT calculations.
- Only phenomenological estimates such as:
  - $\sigma_p \sim 1\,\text{MeV}$, $\sigma_x \sim 10^{-11}\,\text{cm}$ — uranium atom size;
  - $\sigma_p \sim 1 - 10\,\text{keV}$, $\sigma_x \sim 10^{-8} - 10^{-7}\,\text{cm}$ — atomic scale;
  - $\sigma_p \sim 0.1\,\text{eV}$, $\sigma_x \sim 10^{-4}\,\text{cm}$ — pressure broadening.
- Lack of experimental studies.

Daya Bay setup

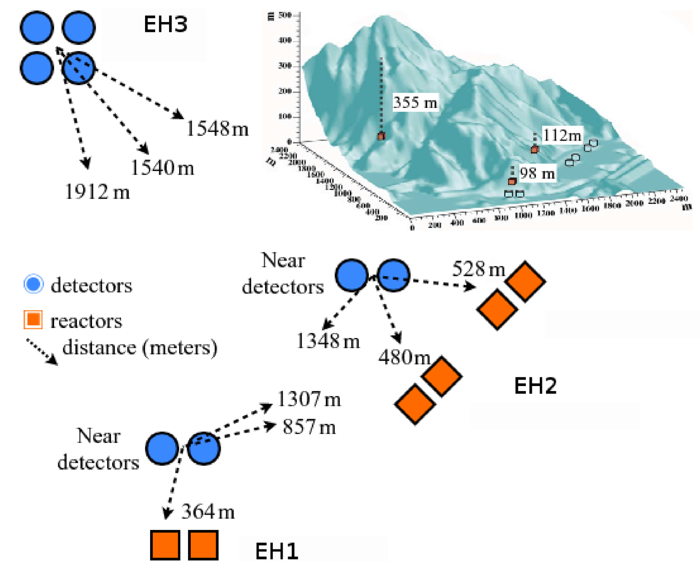
- 8 detectors each with 20 tons of Gd-doped liquid scintillator.
- 6 nuclear reactors each with 2.9 GW of thermal power.
- $\bar{\nu}_e$ detection through IBD

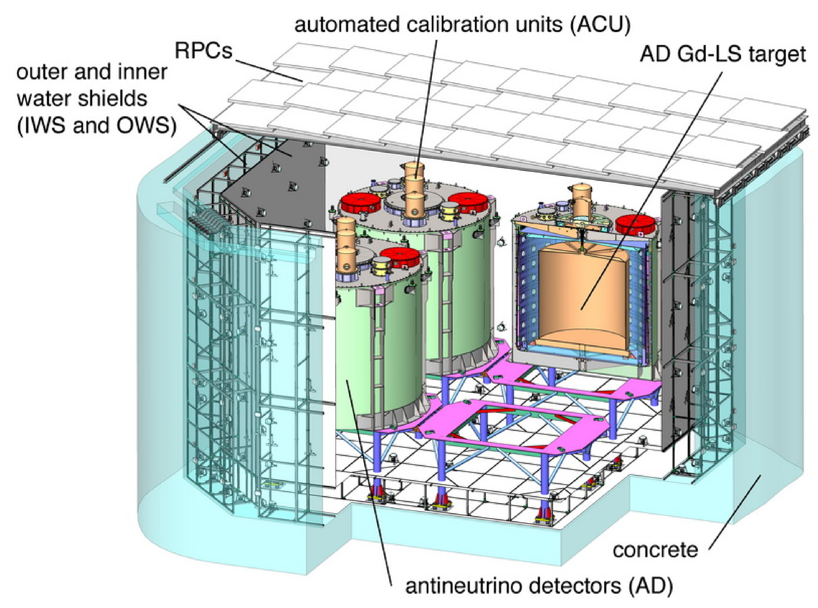
$$\bar{\nu}_e + p \to e^+ + n$$

- Use coincidence of prompt and delayed signals in time to select $\bar{\nu}_e$ events.
- $\bar{\nu}_e$ sample based on 621 days:

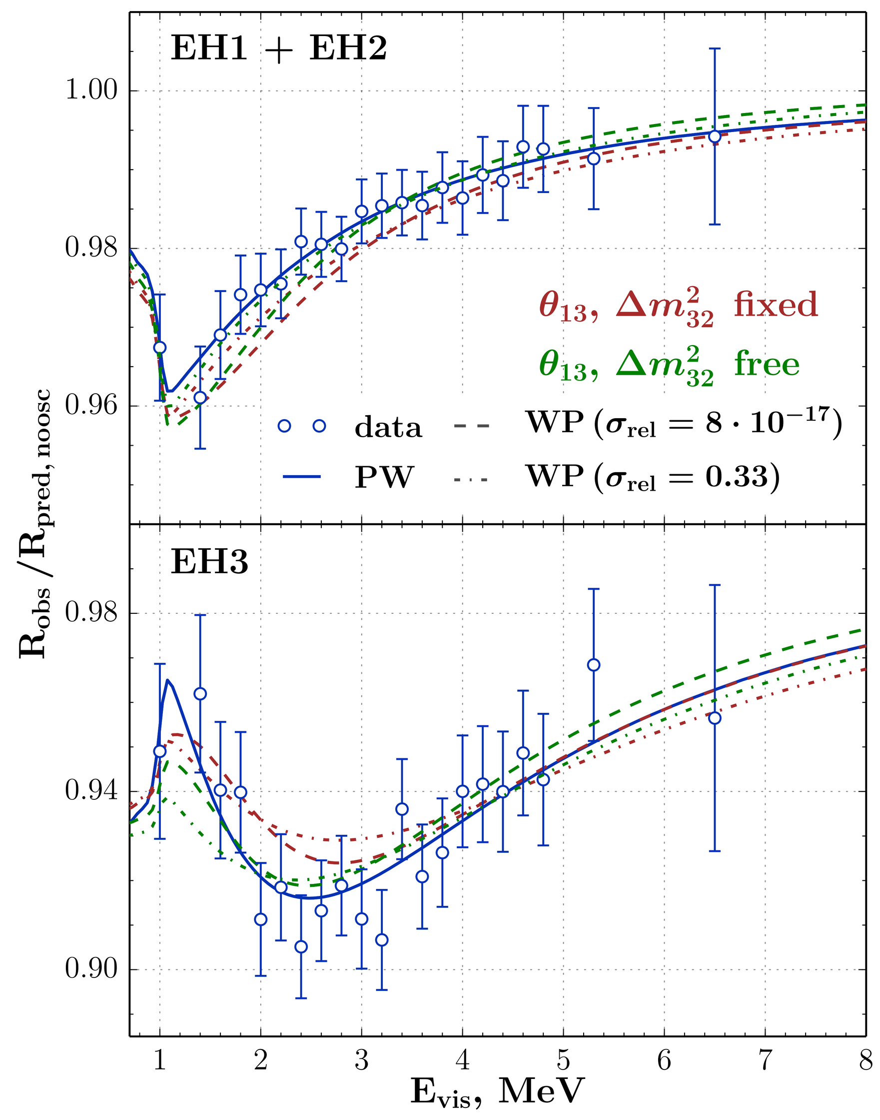
	EH1	EH2	EH3
Events	613813	477144	150255

- Energy resolution $\sim 8\,\%$ at 1 MeV.





Statistical method

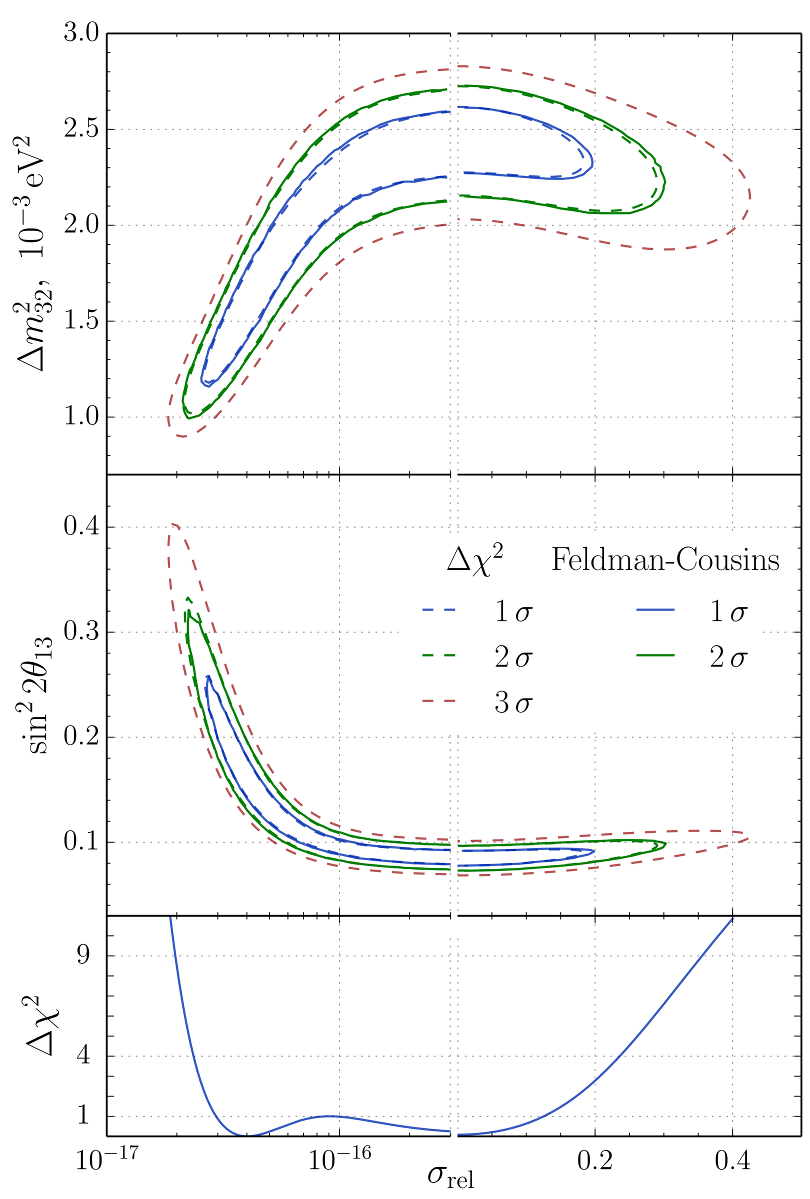


Test statistic is defined as:

$$\chi^2 = (\mathbf{d} - \mathbf{t}(\boldsymbol{\eta}))^T V^{-1}(\mathbf{d} - \mathbf{t}(\boldsymbol{\eta}))$$

- Free parameters:
  - σ_{rel}
  - $\sin^2 2\theta_{13}$
  - Δm^2_{32}
  - Flux normalization N
- Systematical uncertainties are propagated via covariance matrix V.
- Confidence levels are constructed via fixed-level $\Delta\chi^2$ and Feldman-Cousins methods.

Results and Discussion



- There are 3 distinct regions on σ_{rel}:
  - $\sigma_{\text{rel}} < 10^{-16}$ – oscillations are suppressed by D^2.
  - $10^{-16} < \sigma_{\text{rel}} < 0.1$ – no impact on oscillations.
  - $\sigma_{\text{rel}} > 0.1$ – loss of coherence due to spacial separation L^{coh} and dispersion L^{d}.
- Allowed region for σ_{rel} at 95% C.L.:

$$2.38\cdot10^{-17} < \sigma_{\text{rel}} < 0.232$$

- The lower limit can be improved with constraints from reactor cores and detector dimensions. Combined limits are:

$$10^{-11}\,\text{cm} \lesssim \sigma_x \lesssim 2\,\text{m}$$

- The upper limit on σ_{rel} is

$$\sigma_{\text{rel}} < 0.2 \text{ at } 95\% \text{ C.L.}$$

Conclusion

- First experimental limits on σ_{rel} are obtained.
- Insignificance of decoherence effect ensures unbiased measurent of oscillation parameters using the standard approach in Daya Bay.
